

# Controlling Self-Driving Race Cars with Deep Neural Networks

#### UNIVERSITY OF OSNABRÜCK

DEPARTMENT OF NEUROINFORMATICS

**BACHELOR'S THESIS** 

Author: Christoph Stenkamp

Supervisors: Prof. Dr. Gordon Pipa Leon Sütfeld

## Abstract

This Thesis will be written in the next two months, and I'm pretty scared about that. TODO: sobald der komplette text steht bei den Formeln auf die nicht referenziert wird die nummern weg machen (equation\*)

# Preface

This document was written as the author's bachelor thesis at the department of neuroinformatics at the University of Osnabrück during summer 2017 and is an original and independent work by the author Christoph Stenkamp.

Christoph Stenkamp Osnabrück, August 17, 2017

# Acknowledgements

Thanks to my parents, Marie, my supervisors, and my friends....

"There are no surprising facts, only models that are surprised by facts; and if a model is surprised by the facts, it is no credit to that model."

Eliezer Yudkowsky

## List of Abbreviations

The abbreviations used throughout the work are compiled in the following list below. Note that the abbreviations denote the singular form of the abbreviated words. Whenever the plural forms is needed, an s is added. Thus, for example, whereas ANN abbreviates *artificial neural network*, the abbreviation of *artificial neural networks* is written ANNs.

ANN Artificial Neural Network

CNN Convolutional (artificial) Neural Network

CPU Central Processing Unit

DDPG Deep Deterministic Policy Gradient - Network

DQN Deep-Q-Network

GUI Graphical User Interface

MDP Markov Decision Process

POMDP Partially Observed Markov Decision Process

#### Chapter 1

### Introduction

"sollte etwa 10% der Gesamtarbeit ausmachen"

#### 1.1 Motivation

Google's self-driving car, Tesla autopilot, die vision von Ubers autonomous taxis, ...

- 1.1.1 Problem Domain
- 1.1.2 Goal of this thesis
- 1.2 Research Questions
- 1.3 Reading Guidelines

#### 1.4 noclue

As put forward by *Lex Fridman* in his MIT lecture "*Deep Learning for Self-Driving Cars*" the tasks for self-driving cars can be sub-divided into the following categories:

- Localization and Mapping
- Scene Understanding
- Movement Planning
- Driver State

[rrt\* macht halt sowas von 3., end-to-end macht die kiste insgesamt nen bisschen anders]

Semi-autonomous vehicle components: Radar, Visible-light-camera, LIDAR, infrared-camera, stereo vision, GPS/IMU, CAN, Audio

Localization and Mapping: eg.  $file: ///C: /Users/Marie/Downloads/VISAPP_2015_145.pdf$  Scene Understanding/Object Detection: Scene Segentation Network (SegNet) Movement Planning: Previously by stuff like RRT\* (optimization-based control), however reinforcement learning!

End-to-End: NVIDIA Paper

dass Reinforcement Learning ja eigentlich nicht so der beste approach ist Normally when dealing with self-driving cars, there are countless additional issues, each making up a whole new challenge on their own, like wheather conditions

<sup>&</sup>lt;sup>1</sup>MIT 6.S094, course website: http://selfdrivingcars.mit.edu/

(snow, rain, fog), pedestrians, other cars, reflections, merging into ongoing traffic, ... we make it easier here.

Or, according to the Torcs-paper: The racing problem could be split into a number of different components, including robust control of the vehicle, dynamic and static trajectory planning, car setup, inference and vision, tactical decisions (such as overtaking) and fi- nally overall racing strategy. With only a single car on the track, the overall problem can be formalised as a partially observable Markov decision processes.

-> Because we only consider the case of a single car on the track it definitely is a POMDP! seeee next chapter yay

#### **Chapter 2**

# **Reinforcement Learning**

As the task at hand was not only to provide a reinforcement learning agent, but also to convert a game itself into something the agent can successfully play, I will in this chapter go into detail about reinforcement learning in general, giving insights on the specific approach chosen. The descriptions will be kept as general as possible at first, with detailed explanations following in the sections about specific algorithms.

#### 2.1 Reinforcement Learning Problems

Machine Learning can mainly be subdivided into three main categories: Supervised Learning, Unsupervised Learning, and Semi-supervised learning. The first deals with direct classification or regression using labelled data which consists of pairs of datapoints with their corresponding category or value. In unsupervised learning, no such label exists, and the data must be clustered into meaningful parts without any knowledge, for example by grouping objects by similarity in their properties. What will be mainly considered in this thesis will be a certain kind of semi-supervised learning: *Reinforcement learning* (**RL**). In RL, instead of labels for the data, there is a *weak teacher*, which provides feedback on actions performed by the learner.

#### **Markov Decision Processes**

RL can be understood by means of a decision maker (*agent*) performing in an *environment*. The agent makes observations in the environment (its input), takes actions (output) and receives rewards. In contrast to the classical ML approaches, in RL the agent is also responsible for exploration, as he has to acquire his knowledge actively. Thus, a reinforcement learning problem is given if the only way to collect information about the *underlying model* (the environment) is by interacting with it. As the environment does not explicitly provide actions the agent has to perform, its goal is to figure out the actions maximizing its cumulative reward until a training episode ends.

In the classical RL approach, the environment is divided into discrete time steps. If that is the case, the environment corresponds to a *Markov Decision Process* (**MDP**). Formally, a MDP is a 5-tuple  $\langle S, A, P, R, \gamma \rangle$ , consisting of the following:

```
\mathcal{S}-\text{ set of states }s\in\mathcal{S} \mathcal{A}-\text{ set of actions }a\in\mathcal{A} P(s'|s,a)-\text{ transition probability function from state }s\text{ to state }s'\text{ under action }a:\mathcal{S}\times\mathcal{A}\to\mathcal{S} R(r|s,a)-\text{ reward probability function for action }a\text{ performed in state }s:\mathcal{S}\times\mathcal{A}\times\mathcal{S}\to\mathbb{R} \gamma-\text{ discount factor for future rewards }0\leq\gamma\leq1
```

In general, both the state transition function and the reward function may be indeterministic, meaning that neither reward nor the following state are in complete control of the decision maker. Because of that, only expected values are examinable, depending on the random distribution of states. Given both s and s' however, the reward is assumed to be deterministic. I will refer to the actual result of a state transition at discrete point in time t as  $s_{t+1}$  and to the result of the reward function as  $r_t$ . If no point in time is explicitly specified, it is assumed that all variables use the same t.

While an *offline learner* gets as input the problem definition in the form of a complete MDP, where the only task left is to classify actions yielding high rewards from actions giving suboptimal results, the task for an *online reinforcement learning* agent is a lot harder, as it has to learn the MDP itself via trial and error. In the process of reinforcement learning, the agent will encounter states s of the environment, performing actions a. The future state  $s_{t+1}$  of the environment may be indeterministic, but depends on the history of previous states  $s_0, ..., s_t$  as well as the action of the agent  $a_t$ . It is assumed that the *Markov property* holds, which means that a state  $s_{t+1}$  depends only on the current state  $s_t$  and currenct action  $a_t$ :  $p(s_{t+1}|s_t, a_t) = p(s_{t+1}|s_0, a_0, ..., s_t, a_t)$ 

Throughout interacting with the environment, the agent receives rewards r, depending on his action a as well as the state of the environment s. In many RL problems, the full state of the environment is not known to the agent, and it only perceives an observation depending on the environment:  $o_t := o(s_t)^1$ . This is referred to as partial observability, and the corresponding decision process is a partially observable MDP. Additionally, the agent knows when a final state of the environment is reached, terminating the current training episode. For the agent, an episode therefore consists of observations, actions and rewards  $(S \times A \times \mathbb{R})$  until at time  $t_t$  some terminal state  $s_{t_t}$  is reached:

$$Episode := ((s_0, a_0, r_0), (s_1, a_1, r_1), (s_2, a_2, r_2), ..., (s_{t_t}, a_{t_t}, r_{t_t}))$$

#### Value of a state

In the process of reinforcement learning, the agent tries to perform as well as possible in the previously unknown environment. For that, it uses an action-policy  $\pi$ , depending on some parameters  $\theta$ . The policy maps states to actions, which in the case of a *deterministic* policy leads to  $\pi_{\theta}(s) = a$ . Though a stochastic policy is possible, it will not be considered for now<sup>2</sup>. As the agent does not have supervised data on which actions are the ground truth, it must learn some kind of measure for the value of being in a certain state or performing a certain action. The commonly used measure for the value of a state when using policy  $\pi$  can be calculated by the immediate reward this state gives, summed with the expected value of the discounted future reward the agent will archieve by continuing to follow its policy  $\pi$  from this

<sup>&</sup>lt;sup>1</sup>From now on, when the state of the environment is meant, it will be explicitly referred to as  $s_e$ , while s is reserved for the agent's obvervation of the environment  $o(s_e)$ 

<sup>&</sup>lt;sup>2</sup>It is obvious, that the result of both the reward function and the state transition function depend on  $\pi$ . To be explicit about that, I will refer to a reward dependent on  $\pi$  as  $r^{\pi}$  and a state transition dependent on  $\pi$  as  $s^{\pi}$ . If state or reward depends on an explicit action instead, I refer to it as  $r^a$  and  $s^a$ . Whenever not necessary for clarity, I will also drop  $\pi$ 's dependence on  $\theta$ .

state on:

$$V^{\pi}(s_t) := \mathbb{E}_{s \sim \rho^{\pi}} \left[ \sum_{t'=t}^{t_t} (\gamma^{t'-t} * r_{t'}^{\pi}) \right]$$
 (2.1)

As the future rewards depend on future states it can, as already mentioned, only be talked about the expected Value depending on the actual state distribution. This distribution depends on the agents policy, but may still be indeterministic<sup>3</sup>. The discounted state visitation distribution for a policy  $\pi$  is denoted  $\rho^{\pi}$ .

The actual, underlying Value of a state  $V^*(s)$  could accordingly be defined as the value of the state when using the best possible policy, which corresponds to the maximally archievable reward starting in state  $s_t$ :

$$V^*(s_t) := max_{\pi}V^{\pi}(s_t)$$

While *passive learning* simply tries to learn the Value-function  $V^*$  without the need of action selection, an *active reinforcement learner* tries to estimate a good policy that can actually reach those high-value states. If the value of every state is known, then the optimal policy can be defined as the one archieving maximal value for every state of the MDP:  $\pi^* := argmax_{\pi}V^{\pi}(s) \forall s \in \mathcal{S}$ . Knowing what an optimal policy does, the definition of the value  $V^{\pi}(s)$  2.1 can be written recursively as

$$V^{\pi}(s_{t}) = \mathbb{E}_{s \sim \rho^{\pi}} \left[ \sum_{t'=t}^{t_{t}} (\gamma^{t'-t} * r_{t'}^{\pi}) \right]$$

$$= r_{t}^{\pi} + \gamma * \mathbb{E}_{s \sim \rho^{\pi}} \left[ \sum_{t'=t+1}^{t_{t}} (\gamma^{t'-t} * r_{t'}^{\pi}) \right]$$

$$= r_{t}^{\pi} + \gamma * V^{\pi}(s_{t+1})$$
(2.2)

This relation is known as the *Bellman Equation*, which allowed for the birth of dynamic programming<sup>4</sup>.

#### Value of an action

While the definition of a state-value is useful, it alone does not help an agent to perform optimally, as neither the successor function P(s'|s,a), nor the reward function R(r|s,a) are known to the agent. While so-called *model-based* reinforcement learning (also referred to as *Certainty Equivalence*) tries to learn both of those explicitly to reconstruct the entire MDP, *model-free* agents use a different measure of quality: the *Q-value*. It represents the expected value of performing action  $a_t$  in a state  $s_t$ , afterwards following the policy  $\pi$ :

$$Q^{\pi}(s_t, a_t) := \mathbb{E}_{s \sim \rho^{\pi}} \left[ r_t^{a_t} + \gamma * V^{\pi}(s_{t+1}^{a_t}) \right]$$
 (2.3)

<sup>&</sup>lt;sup>3</sup>That is one of the reasons to discount future rewards: The agent cannot be fully sure if it actually reaches the states it strives for. Also, using the discounted reward hopefully helps making the agent perform good actions as quickly as possible.

<sup>&</sup>lt;sup>4</sup>Dynamic programming is another solution strategy for MDPs. In contrast to RL however, it requires the complete MDP as input to find an optimal policy, which cannot be given in many relevant situations.

With the Q-value  $Q^*$  of the optimal policy accordingly

$$Q^*(s_t, a_t) = \mathbb{E}_{s \sim \rho^{\pi}} [r_t^{a_t} + \gamma * V^*(s_{t+1}^{a_t})]$$
  
=  $max_{\pi} Q^{\pi}(s_t, a_t)$ 

For the Q-value, the Bellman equation holds as well: If the correct Q-value under policy  $\pi$ ,  $Q^{\pi}(s_{t+1}, a_{t+1})$ , was known for all possible actions at time t, then the optimal action is the one maximizing the sum of immediate reward and corresponding Q-value. This is because of the definition of Bellman's *Principle of Optimality*, which states that "An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision" (quote [3]). Thanks to the principle of optimality, the value of our decision problem at time t can be re-written in terms of the immediate reward at t plus the value of the remaining decision problem at t+1, resulting from the initial choices:

$$Q^{\pi}(s_t, a_t) = \mathbb{E}_{s \sim \rho^{\pi}} \left[ r_t^{a_t} + \gamma * Q^{\pi}(s_{t+1}, \pi(s_{t+1})) \right]$$
 (2.4)

As the Value of a state is defined as the maximally archievable reward from that state, the relation between Q and V can be expressed as

$$V(s_t) = \max_{a_t} Q(s_t, a_t) \tag{2.5}$$

#### Quality of a policy

Any agent's goal is to find a policy that can follow the trajectory of the state distribution with the highest expected reward. If the actual Q-value for each action of each state was known, then the optimal policy can be defined as the one taking the optimal action in each state:

$$\pi^* = argmax_a Q^*(s, a) \forall s, a \in \mathcal{S} \times \mathcal{A}$$
 (2.6)

This policy guarantees maximum future reward at every state. Note however, that finding  $argmax_aQ(s,a)$  is only easily possible if  $\mathcal{A}$  is discrete and finite (more on that later).

As for the actual performance of a policy, a useful measure is the *performance* objective J. It integrates over the whole state space  $\mathcal S$  with each state s weighted by its distribution due to policy  $\pi$ . As only non-stochastic policies are considered here, integration over the action space  $\mathcal A$  is not necessary. The integral can, as shown by [13], be expressed by the expectation of the Value of states following the distribution  $s \sim \rho^{\pi}$ :

$$J(\pi) = \int_{\mathcal{S}} \rho^{\pi}(s) V^{\pi}(s) ds \tag{2.7}$$

$$= \mathbb{E}_{s \sim \rho^{\pi}} \left[ V^{\pi}(s) \right] \tag{2.8}$$

$$= \mathbb{E}_{s \sim \rho^{\pi}} \left[ Q^{\pi}(s, \pi(s)) \right] \tag{2.9}$$

We assume for now that once an agent knows  $Q^*$ , it can simply follow the policy that always takes the action yielding the highest value for every state (the *greedy* policy)<sup>5</sup>.

<sup>&</sup>lt;sup>5</sup>in fact, the agent cannot act only according to the greedy policy, as it will need to *explore* the environment first. The problem of exploration will be considered later in this thesis.

Thus, the goal of a model-free RL agent is to get a maximally precise estimate of  $Q^*$ . To do that, it does not need to explicitly learn the reward- and transition function, but instead can model the Q-function directly. In RL settings with a highly limited amount of discrete states and actions, the respective Q-function estimate can be specified as a lookup table, whereas for areas of interest, the function is estimated using a nonlinear function approximator. The agent's approximation of  $Q^{\pi}$  will be denoted  $\hat{Q}^{\pi}$ .

Throughout exploration of the environment, the agent collects more information about it, continually updating its estimate  $\hat{Q}^{\pi}$ . For that, it uses samples from its episodes of interacting with the environment.

#### 2.2 Temporal difference Learning

Throughout the process of reinforcement learning, the agent continually improves its estimates  $\hat{Q}^{\pi}$  of  $Q^{\pi}$ . The loss of its current estimate could be seen as the squared difference  $(\hat{Q}^{\pi} - Q^{\pi})^2$ , however as the agent has no knowledge of  $Q^{\pi}$ , it needs some way of approximating it. For that, a Q-learning agent performs *iterative approximation*, using the information about the environment, to continually update its estimates of  $Q^{\pi}$ . Using the recursive definition of a Q-value given in the Bellman equation 2.4 allows for a technique called *temporal difference learning*[14]: At time t+1, the agent can compare its estimate of the Q-function of the last step,  $\hat{Q}^{\pi}(s_t, a_t)$ , with a new estimate using the new information it gained from the environment:  $r_{t+1}$  and  $s_{t+1}$ . Because of the newly gained information from the underlying MDP, the new estimate will be closer to the actual function  $Q^{\pi}$  than the original value:

$$\hat{Q}^{\pi}(s_t, a_t) = r_t + \mathbb{E}_{s \sim \rho^{\pi}} \left[ \gamma * \max_{a_{t+1}} \hat{Q}^{\pi}(s_{t+1}, a_{t+1}) \right]$$
(2.10)

$$\approx r_t + \gamma * r_{t+1} + \mathbb{E}_{s \sim \rho^{\pi}} \left[ \gamma^2 * \max_{a_{t+2}} \hat{Q}^{\pi}(s_{t+2}, a_{t+2}) \right]$$
 (2.11)

Keeping in mind that  $\hat{Q}^{\pi}$  is only an estimator of the  $Q^{\pi}$ -values of the underlying model, it becomes clear that equation 2.11 is closer to the actual  $Q^{\pi}$ , as it incorporates more information stemming from the model itself.

In temporal difference learning, the mean-squared error of the *temporal difference* from this Bellman equation,  $r_t + \gamma * Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)$ , gets minimized via iterative approximation. Even though  $r_t + \gamma * \hat{Q}^{\pi}(s_{t+1}, a_{t+1})$  also uses an estimate, it contains more information from the environment, and is thus a *more informed guess* than  $\hat{Q}^{\pi}(s_s, a_s)$ . That makes it reasonable to substitute the unknown  $Q^{\pi}(s_{t+1}, a_{t+1})$  by  $\hat{Q}^{\pi}(s_{t+1}, a_{t+1})$ .

It is noteworthy, that each update of the Q-function using the temporal difference will affect not only the last prediction, but all previous predictions.

#### **SARSA**

The new knowledge about the environment can be incorporated in two different ways. For the first method, the agent samples a full tuple of  $\langle s_t, a_t, r_t, s_{t+1}, a_{t+1} \rangle$  from its interaction with the environment, to then calculate the temporal difference error in non-terminal states as  $TD := (r_t + \gamma * \hat{Q}^{\pi}(s_{t+1}, a_{t+1})) - \hat{Q}^{\pi}(s_t, a_t)$ . This algorithm of calculating the temporal difference error is known as SARSA, and it is an example of *on-policy* temporal difference learning. In on-policy learning, the

agent uses its own policy in every estimate of the Q-value. If the policy of the agent is not stochastic, this method can however lead to it getting stuck in local optima.

#### **Q-learning**

In contrast to SARSA stands the *Q-learning* algorithm [16]. Q-learning does not need to sample the action  $a_{t+1}$ , as it calculates the Q-update at iteration i using the best possible action in state  $s_{t+1}^6$ .

As the previous definition of Q-values was only correct in non-terminal states, a case differentiation must be introduced for terminal- and non-terminal states. In the following,  $y_t$  will stand for the updated estimate of the Q-value at t, sampling the necessary states, rewards and actions from interaction with the environment, almost resulting in the formula found in [10]. To express its dependence on the policy  $\pi$ , it will be superscripted by it:

$$y_t^{\pi} = \begin{cases} r_t & \text{if } t = t_t \\ r_t + \gamma * \max_{a_{t+1}} \hat{Q}^{\pi}(s_{t+1}, a_{t+1}) & \text{otherwise} \end{cases}$$
 (2.12)

The temporal difference error for time *t* is accordingly defined as

$$TD_t := y_t^{\pi} - \hat{Q}^{\pi}(s_t, a_t) \tag{2.13}$$

A Q-learning agent must thus observe a snapshot of the environment, consisting of the following input:  $\langle s_t, a_t, r_t, s_{t+1}, t+1 == t_t \rangle$  (where the last element is the information if state  $s_{t+1}$  was a terminal state). That information is then used to calculate the temporal difference error.

In very limited settings, using the above error straight away allows for the updaterule in simple Q-learners: Consider an agent, specifying its approximation of the Qfunction (his *model*) with a lookup-table, initialized to all zeros. It is proven by [17] that for finite-state Markovian problems with nonnegative rewards the update-rule for the Q-table (with  $0 \le \alpha \le 1$  as the learning rate)

$$\hat{Q}_{i+1}^{\pi}(s_t, a_t) \leftarrow \alpha * \left(r_t^{a_t} + \gamma * \hat{Q}_i^{\pi}(s_{t+1}^{a_t}, a_{t+1})\right) + (1 - \alpha) * \hat{Q}_i^{\pi}(s_t, a_t)$$
(2.14)

converges to the optimal  $Q^*$ -function, making the greedy policy  $\pi^*$  optimal<sup>7</sup>. Note, that the same update rule as for the Q-function could be performed for the V-function.

In contrast to SARSA, Q-learning is an *off-policy* algorithm, meaning that the policy it uses in its evaluation of the Q-value is not necessarily the one it actually uses: When calculating the temporal difference error, the agent considers Q-values  $\hat{Q}^{\pi_{greedy}}(s,a)$ , based on  $\pi_{greedy}(s) = argmax_{a'}\hat{Q}(s,a')$ , as better approximation of the real action-value function  $Q^{\pi}(s,a)$ . Therefore, it learns about  $\pi_{greedy}$ , which is to always take the action promising maximum Value. Because following the deterministic  $\pi_{greedy}$  does not allow for *exploration*, this is not the policy the agent actually pursues.

When using off-policy algorithms with  $\pi$  as the policy we learn about and  $\beta$  as the policy we act upon, our performance objective  $J(\pi)$  must change, as it must incorporate that while the value of a state is calculated using  $\pi$ , the distribution of

<sup>&</sup>lt;sup>6</sup>A slight deviation from this is double-Q-learning, an architecture I will go into detail about later on.

<sup>&</sup>lt;sup>7</sup>Of course the agent will need some kind of exploration technique first, more on that later

states follows from policy  $\beta$ :

$$J_{\beta}(\pi) = \mathbb{E}_{s \sim \rho^{\beta}} \left[ Q^{\pi}(s, \pi(s)) \right] \tag{2.15}$$

The process of reinforcement learning consists of two steps: *policy evaluation*, where the agent evaluates its current policy according to the knowledge gained from the environment, and based on that *policy improvement*. In the standard Q-learning considered here, those steps are interleaved, leading to a form of *generalized policy iteration*: the Q-learner learns its action value-function and its policy simultaneously. After updating its Q-function estimate via the temporal difference error, the agent updates its policy to be a *soft* version of the greedy policy  $\pi_{i+1}(s) := argmax_{a'}Q^{\pi_i}(s,a')\forall s \in \mathcal{S}$ , while keeping a mechanism allowing for exploration. Learning with this approach is however generally limited:  $argmax_{a'}Q(\cdot,a')$  can only easily be found in settings where the action space  $\mathcal{A}$  is finite and discrete, as it requires a global maximization over all possible actions. In a later section, I will go into detail about another architecture which does circumvents those problems by splitting up policy evaluation and policy improvement explicitly.

As there are also relevant situations in which discrete actions  $\mathcal{A} \subseteq \mathbb{N}^n$  are sufficient, I will stick to those situations for now. Also in these circumstances, a Q-learner using tables as Q-function-approximator reaches its limits really fast, as the state space  $\mathcal{S}$  may also be continuous or simply too big for a table to be useful. If that is the case, an update rule like in equation 2.14 becomes irrelevant quickly. Instead, a better idea is to use the definition of the temporal difference error to define a loss function, which is to be minimized throughout the process of RL. A commonly used loss-function is the L2-Loss, which allows for gradient descent, updating the parameters of the Q-function into the direction of the newly acquired knowledge. In this case, it may also be useful to calculate the loss of a batch of temporal differences simultaneously, which will be elaborated lateron in more detail. The L2-Loss for batch batch with model-parameters  $\theta_i$ , making up the policy  $\pi_{\theta_i}$  is thus defined as the following:

$$L_{batch}(\theta_i) := \mathbb{E}_{s,a,r \sim batch} \left[ \left( y_{batch}^{\pi_{\theta_i}} - \hat{Q}_{batch}^{\pi_{\theta_i}}(s,a) \right)^2 \right]$$
 (2.16)

#### 2.3 Q-Learning with Neural Networks

To understand this section, basic knowledge on how *Artificial Neural Networks* (**ANNs**) work and what they do is presupposed. Specifically, knowledge of *Convolutional Neural Networks* (**CNNs**)[18], mainly used in image processing, is required. As mentioned before, it is (in theory) not only possible to use a Q-table to estimate the  $Q^{\pi}$ -function, but any kind of function approximator. Thanks to the universality theorem, it is known that ANNs are an example of such<sup>8</sup>. The defining feature of ANNs in comparison to other Machine Learning techniques is their ability to store complex, abstract representations of their input when using a *deep* enough architecture.

<sup>&</sup>lt;sup>8</sup>For a proof of the universality theorem, I refer to chapter 4 of Michael A. Nielsen's book "Neural Networks and Deep Learning", Determination Press, 2015. The referred chapter is available at http://neuralnetworksanddeeplearning.com/chap4.html

#### 2.3.1 Deep Q-learning

The reason to use neural function approximators instead of a simple Q-table approach for reinforcement learning problems is easy to see: While for a Q-table the states and actions of the Markov Decision Process must be discrete and very limited, this is not the case when using higher-level representations. If the agent's observation of a state of the game is high-dimensional (like for example an image), the chance for an agent to observe the exact same observation twice is extremely slight. Instead, an Artificial Neural Network can learn a higher-level representation of the state, grouping conceptually similar states, and thus generalize to new, previously unseen states. It is no surprise that the success of *Deep-Q-Networks* started its journey shortly after the introduction of CNNs, which are able to learn abstract representations of similar images and by now used in countless Computer Vision Applications.

Deep-Q-Network (**DQN**) refers to a family of off-policy, online, active, model-free Q-learning algorithms for discrete actions using Deep Neural Networks. Using ANNs as function approximators for the agent's model of the environment requires a Loss function depending on the Neural Network parameters, specified by  $\theta$ . These weights correspond to the parameters of the  $\hat{Q}$ -function of the agent. As previously mentioned, this kind of Q-learning defines its policy straight-forward, depending on the  $argmax_a$  of the Q-function. I will therefore replace the dependence of  $\hat{Q}^{\pi}(s,a)$  on  $\pi$  by a dependence on its parameters:  $\hat{Q}(s,a;\theta_i)$ . The update rule in Deep Networks depends on the gradient with respect to its loss,  $\nabla_{\theta_i} L(\theta_i)$ . As the DQN-architecture only considers discrete actions, there is one change that can be made in the definition of the Q-function: instead of giving both the state s and the action s as input to the network, in DQNs only the state is input to the network, with the network returning a separate Q-value for each actions s and s and the inference, as one forward step is enough to calculate the Q-value of all actions in a certain state.

While there are attempts to use Artificial Neural Networks for Q-learning as early as 1994[11], some key components of modern Deep-Q-Networks were missing, leading to satisfactory performance only in very limited settings. In standard online RL tasks, the update step minimizing the loss specified in 2.16 is performed not for a batch, but for each time t right after the observation occured to the agent. In those situations, the current parameters of the policy determine the next sample the parameters are trained on. It is easy to see, that those consecutive steps of MPDs tend to be correlated: It is very likely, that the maximizing action of time t is similar to the one at t+1. Consecutive steps of an MDP are not representative of the distribution the whole underlying model. ANNs require independent and identically distributed samples, which is not given if the samples are generated sequentially. As shown by [7], the update using gradient descent is prone to feedback loops and thus oscillation in its result, thus never converging to an optimal  $Q^{\pi}$ -function.

It was not until *Deepmind's* famous papers in 2013[9] and 2015[10], that those issues were successfully adressed. One important step when using ANNs instead of Q-tables is to perform stochastic gradient descent using minibatches. In every gradient descent step of the Neural Network, neither only the last temporal difference error  $TD_t$  is considered (leading to oscillations), nor the entire sequence  $TD_0,...,TD_{t_t}$  (because batch updates are not time-efficient in ANNs). Instead, as usual when dealing with ANNs, minibatches are sampled from the set of all observations. When performing the gradient descent step, the weights for the target  $y_t$  are fixed, making

the minimization of the temporal difference error a well-defined optimization problem (with clear-cut target values as in supervised learning) during the learning step.

The two important innovations introduced in the DQN-architecture were the use of a *target network* as well as the technique of *experience replay*, which in combination successfully solved the problem of oscillating and non-converging action-value functions, even though still no formal mathematical proof of convergence is given.

#### **Experience Replay**

As mentioned above, learning only from the most recent experiences biases the policy towards those situations, limiting convergence of the Q-function. To adress this issue, the DQN uses an experience replay memory: Every percept of the environment (the  $\langle s_t, a_t, r_t, s_{t+1}, t+1 == t_t \rangle$  - tuple) is added to a limited-size memory of the agent. When then performing the learning step, the agent samples random minibatches from this memory to perform learning on a maximally uncorrelated sample of experiences. In the original definition of DQN, those minibatches are drawn uniformely at random, while as of today, better techniques for sampling those minibatches are available[12], increasing the performance of the resulting algorithm significantly.

#### **Target Networks**

During the training procedure, the DQN-algorithm uses a separate network to generate the target-Q-values which are used to compute the loss (eq. 2.16), necessary for the learning step of every iteration. The intuition behind why that is necessary is, that the Q-values of the *online network* shift in such a way, that a feedback loop can arise between the target- and estimated Q-values, shifting the Q-value more and more into one direction. To lessen the risk of such feedback loops, the DQN algorithm introduced the use of a second network for calculating the loss: the *target network*. This is only periodically updated with the weights of the online network used for the policy, which reduces the risk of correlations in the action-value  $Q_t$  and the corresponding target-value  $y_t$  (see equation 2.12).

The use of these two techniques leads to the Q-learning update rule, using the loss as put forward in [10]:

$$L_{i}(\theta_{i}) = \mathbb{E}_{\langle s_{t}, a_{t}, r_{t}, s_{t+1} \rangle \sim U(D)} \left[ \left( r + \gamma * max_{a_{t+1}} \hat{Q}(s_{t+1}, a_{t+1}; \theta_{i}^{-}) - \hat{Q}(s_{t}, a_{t}; \theta_{i}) \right)^{2} \right]$$
(2.17)

Where i stands for the current network update iteration,  $\theta_i$  for the current weights of the target network (updated every C iterations to be equal to the weights of the online network  $\theta_i$ ),  $Q(\cdot,\cdot;\theta)$  for the Q-value dependend on a ANN using the weights  $\theta$ ,  $\mathbb{E}[\cdot]$  for the expected value in an indeterministic environment, D for the contents of the replay memory of length |D| containing  $\langle s_t, a_t, r_t, s_{t+1} \rangle$ -tuples, and  $U(\cdot)$  for a uniform distribution.

As is the case with the experience replay mechanism, the usage of a target network was improved as well – modern algorithms do not perform a hard update of the target network every C steps, but instead perform *soft target network updates*, where every iteration, the weights of the target network are defined as  $\theta_i^- := \theta_i * \tau + \theta_i^- * (1 - \tau)$  with  $0 < \tau \ll 1$ , first introduced in [8]. This improves the stability of the algorithm even more.

As a pseudocode for the DQN-architecture is already stated in the corresponding paper [10], listing it again here would be superflous. Instead, I try to compare the pseudocode with the code of my actual implementation using Python and Tensorflow in appendix A.1. In the first two pages of the appendix, the necessary definitions of agent and network structure are introduced, before in page 28 there is the actual comparison between the pseudocode and its correspondences in the actual code, namely the \_\_init\_\_ , inference and q\_learn -functions of the model-class. Note that the blue lines of the pseudocode correspond to difference from the original DQN in favor of later improvements.

#### 2.3.2 Double-Q-Learning

It is well known that Q-learning tends to ascribe unrealistically high Q-values to some action-state-combinations. The reason for this is, that to estimate the value of a state  $s_i$  it includes a maximization step over estimated action values  $Q(s_i, a)$ , where naturally, overestimated values are preferred over underestimated values. It is not possible that Q-value-estimates are completely precise: estimation errors can occur due to environmental noise, inaccuracies in function approximation (consider a flexible ANN trained on only a small sample so far - the ANN will overfit by covering all samples precisely. This overfitting leads to steep curves, over- or underestimating many values in between) and many other issues. Because Q-learning uses in every estimate of the value of a state  $s_i$  the maximum Q-value of state  $s_{i+1}$ , only those estimates are propagated where the noise of the estimation is in a positive direction. Because of that, state  $s_{i-1}$  will have the accumulated upward noise from both state  $s_i$  and  $s_{i+1}$ , and so forth. This leads to unrealistically high action-values. While this would not constitute a problem if all Q-values would be uniformly overestimated, [5] showed that its very likely that the Q-value  $Q(s_i, a)$  for only some actions a is overestimated – which changes the result of the  $argmax_a$  operation and thus leads to biased policies. They also show that the drop in DQN performance correlates with this overestimation of actions.

The solution suggested by [5] is called *Double-Q-learning*. In its original definition without using Neural Networks as function approximators, a double-Q-learner learns two value functions in parallel, by letting each experience update only one of the two value functions at random. For each update then, one function is used to determine the greedy policy, while the other is used to determine the value of this policy. The authors proved that the lower bound for the overestimation of action-value,  $max_{a'}Q^{\pi}(s,a') - V^*(s)$ , is > 0 for the standard Q-learning update rule, whereas it is 0 in the case of DoubleQ. Additionally they showed that these overestimations are indeed harmful by showing the superiority of a DoubleQ-learner in comparison with a normal Q-learner.

Deep-Double-Q-Learning (**DDQN**) takes the Double-Q idea to the existing framework of Deep-Q-learning: Overerstimations are reduced by decomposing the *max*-operation into *action selection* and *action evaluation*. Instead of introducing a second value function, DDQN re-uses the target-network of the DQN architecture in place of the second value function. Although online network and target network are not

<sup>&</sup>lt;sup>9</sup>"In DoubleQ, we still use the greedy policy to select actions, however we evaluate how good it is with another set of weights". The intuition behind that is, that the probability of both value-functions always over-estimating the same actions is basically zero.

fully decoupled, experiments showed that it provides a good candidate for independent action evaluation, without the need of additional functions. The technique of DDQN is thus to still use the online network to choose an action (evaluate the greedy policy according to the online network), but the target network to generate the target Q-value for that action (to estimate its value). As shown by [5], DDQN improves over DQN both in terms of value accuracy and in terms of the actual quality of the policy.

It can be seen in appendix A.1 how small the actual change to normal DQN is: The only difference is the usage of the target network in line 21 (marked in blue).

#### 2.3.3 Dueling Q-Learning

**Using Recurrent Networks** 

#### 2.4 Policy Gradient Techniques

#### 2.4.1 Actor-Critic architectures

The previously introduced technique, a direct adaptation of the Q-learning algorithm [14][16], is a kind of *generalised policy iteration*, where the policy evaluation and policy improvement happen in the same step. The algorithms learns via temporal differences the state-action value  $Q^{\pi_{greedy}}(s,a)$  for the states it encountered with its current policy  $\pi$ . It then updates  $\pi$  to a soft version of that greedy policy  $\pi_{i+1}(s) := soft(argmax_aQ^{\pi_{greedy}}(s,a) \forall s \in \mathcal{S})$ , where the soft-function ensures appropriate exploration. Learning the Q-function and the policy simulatenously is however generally limited:  $argmax_aQ(\cdot,a)$  can only easily be found in settings where the action space A is finite and discrete, as it requires a global maximization over all possible actions. While discretizing the action space is possible, it gives rise to the *curse of dimensionality*, especially when the discretization is fine grained. An iterative optimization process like the argmax-operation would thus likely be intractable.

However in a lot of scenarios, the action space is not discrete, but continuous:  $A \subseteq \mathbb{R}^n$ . In such situations, the alternative is to move the policy into the *direction of the gradi*ent of Q. For that, it is necessary to model the policy explicitly with another function approximator. This gives rise to actor-critic architectures, where both policy and Qfunction are explicitly modeled: The critic uses temporal differences to estimate the Q-value of states  $s \in \mathcal{S}$  and actions  $a \in \mathcal{A}$ . If the critic were perfect, it would return the true action-value function of the policy  $\pi$ ,  $Q^{\pi}(s,a)$ . As that is not the case however, it is in fact similar to the Bellman-function-approximator from previous sections. In contrast to those however, the policy is now explicitly modeled by the actor. In the case of a stochastic policy, it would be represented by a parametric probability distribution  $\pi_{\theta}(a|s) = \mathbb{P}[a|s;\theta]$ , however here we only consider the case of deterministic policies  $a = \pi_{\theta}(s)$ , which takes the necessity of averaging over all possible actions of our policy. Note however, that using deterministic policies will (again) lead to the necessesity of off-policy algorithms, as a purely deterministic policy does not allow for adequate exploration of state-space  $\mathcal S$  or action-space  $\mathcal A$ . Thus, to measure the performance of our policy, we must use function 2.15, which averages over the state distribution of our behaviour policy  $\beta \neq \pi$ .

To learn both actor and critic, actor-critic algorithms rely on a version of the *policy gradient theorem*, which states a relation between the gradient of the policy and

the gradient of the performance function 2.15. The idea behind policy gradient algorithms is accordingly to adjust the parameters  $\theta$  of the policy in the direction of the performance gradient  $\nabla_{\theta} J(\pi_{\theta})$ , as moving uphill into the direction of the performance gradient corresponds to maximizing the global performance of the policy.

#### **Deterministic Policy Gradient**

The idea in the *Deterministic Policy Gradient* (**DPG**) technique is to use a relation between the gradient of the (deterministic) policy (estimated by the actor), and the gradient of the action-value function Q. The critic estimates the Q-function using a differentiable function approximator, and then the actor updates the *policy* parameters in the direction of the gradient of Q, rather than to maximize it globally.<sup>10</sup>

The deterministic policy gradient theorem, put forward in [13], uses the chain rule to state a relation between the gradient of the performance objective of a policy  $J(\pi)$  (see equation 2.15) and the gradients of the policy-function  $\pi$  and the Q-function Q.

$$\nabla_{\theta} J_{\beta}(\pi_{\theta}) \approx \int_{\mathcal{S}} \rho^{\beta}(s) \nabla_{\theta} \pi_{\theta}(a|s) Q^{\pi}(s, a) ds$$

$$= \mathbb{E}_{s \sim \rho^{\beta}} \left[ \nabla_{\theta} \pi_{\theta} Q^{\pi}(s, \pi_{\theta}(s)) \right]$$

$$= \mathbb{E}_{s \sim \rho^{\beta}} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q^{\pi}(s, a) \Big|_{a = \pi_{\theta}(s)} \right]$$
(2.18)

This shows, that the gradient of the performance-objective of the policy with respect to its parameters (this is what we want to maximize) corresponds oth the gradient of the policy with respect to its weights times the gradient of the Q-function w.r.t. the actions.

In practice, the true function  $Q^{\pi}(s,a)$  is unknown and must be estimated. For that, the critic uses Q-learning as explained in the sections above. It is however important, that the approximation  $\hat{Q}\pi(s,a)$  is *compatible*, preserving the true gradient  $\nabla_a Q^{\pi}(s,a) \approx \nabla_a \hat{Q}^{\pi}(s,a)$ . This is the case when its gradient w.r.t. its weights is orthogonal to the gradient w.r.t. its actions, and the critic minimizes the mean-squared error between the gradient of  $Q^{\pi}$  and  $\hat{Q}^{\pi}$ . Both conditions are however approximately fulfilled when using a critic that finds  $Q^{\pi}(s,a) \approx \hat{Q}^{\pi}(s,a)$ .

What this results in, is a *compatible off-policy deterministic actor critic* algorithm. In the first step of this algorithm, the critic calculates the temporal difference error to update its own parameters like in previous sections, and then the actor updates its parameters in the direction of the critic's action-value gradient:

$$TD_t = r_t + \gamma Q^w(s_{t+1}, \pi_\theta(s_{t+1})) - Q^w(s_t, a_t)$$
(2.19)

$$w_{t+1} = w_t + \alpha_w * TD_t * \nabla_w Q^w(s_t, a_t)$$
(2.20)

$$\theta_{i+1} = \theta_t + \alpha_\theta * \nabla_\theta \pi_\theta(s_t) \nabla_a Q^w(s_t, a_t) \Big|_{a = \pi_\theta(s)}$$
(2.21)

When updating the policy, its parameters  $\theta_{i+1}$  are updated in proportion to the gradient  $\nabla_{\theta} J(\pi_{\theta})$ . Because of the deterministic policy gradient theorem 2.18, this

As however ach state suggests a different direction, one must average by taking the expectation w.r.t. the state distribution  $\rho^{\pi}(s)$ :

$$\theta_{i+1} = \theta_i + \alpha * \mathbb{E}_{s \sim \rho^{\pi_i}} \left[ \nabla_{\theta} J(\pi_{\theta}) \right]$$
 (2.22)

<sup>&</sup>lt;sup>10</sup> "The critic estimates the action-value function while the actor ascends the gradient of the action-value-function" (quote [13])

Using the chain rule, this can be decomposed into the gradient of the action-value w.r.t. the actions and the gradient of the policy w.r.t. the policy parameters:

$$\theta_{i+1} = \theta_i + \alpha * \mathbb{E}_{s \sim \rho^{\pi_i}} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_a Q^{\pi_i}(s, a) \big|_{a = \pi_{\theta}(s)} \right]$$
 (2.23)

Silver et al [13] proved that it is not necessary to compute the gradient of the state distribution, and that this [line above] update follows precisely the gradient of the performance objective:

$$\nabla_{\theta} J(\pi_{\theta}) = \mathbb{E}_{s \sim \rho^{\pi_i}} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_a Q^{\pi}(s, a) \Big|_{a = \pi_{\theta}(s)} \right]$$
(2.24)

They say themselves that these algorithms may have convergence issues in practice, due both to bias introduced by the fucntion approximator, as well as instablilities caused by off-policy learning.

Off-policy deterministic actor-critic now learns a deterministic target policy  $\pi(s)$  from trajectories generated by an arbitrary stochastic policy,  $\beta(a|s) = \mathbb{P}[a|s]$ . Now, the performance objective is the value function of the target policy Now we re-define the performance objective again by the value function of the target policy, averaged over the state distribution of the behaviour policy:

$$J_{\beta}(\pi_{\theta}) = \mathbb{E}_{s \sim \rho^{\beta}} \left[ V_{\ell}^{\pi} s \right] \tag{2.25}$$

$$= \mathbb{E}_{s \sim \rho^{\beta}} \left[ Q^{\pi}(s, \pi(s)) \right] \tag{2.26}$$

OOOKAY; lets try this again. As before, we want to find a policy maximizing some measure of discounted future rewards, for which we will again consider the Value of a state, as defined in 2.1. A performance objective of our policy is now the value of the state, according to our policy. This performance objective depends however on the actual state distribution (which is, as defined, indeterministic), as well as the action distribution of our policy, which may well be stochastic. In the following, we will consider only deterministic policies. While that takes the necessity of finding the exptected value of that distribution, it only allows for off-policy algorithms, where the distribution of the states depends on another, stochastic, policy than the one we actually learn. To get the actual performance objective, we must thus average the known value function over the state distribution of our behaviour policy  $\beta \neq \pi$ :

$$J_{\beta}(\pi_{\theta}) = \int_{S} \rho^{\beta}(s) V^{\pi}(s) ds \tag{2.27}$$

$$= \mathbb{E}_{s \sim \rho^{\beta}} \left[ V^{\pi}(s) \right] \tag{2.28}$$

$$= \mathbb{E}_{s \sim \rho^{\beta}} \left[ Q^{\pi}(s, \pi(s)) \right] \tag{2.29}$$

The gradient of that is now

$$\nabla_{\theta} J_{\beta}(\pi_{\theta}) \approx \mathbb{E}_{s \sim \rho^{\beta}} \left[ \nabla_{\theta} \pi_{\theta}(s) \nabla_{a} Q^{\pi}(s, a) \Big|_{a = \pi_{\theta}(s)} \right]$$
 (2.30)

because of the deterministic policy gradient theorem put forward in [13]. What they then do is to develop an actor-critic algorithm that updates the policy in the direction of that. Again, they replace  $Q^{\pi}(s,a)$  by  $Q^{w}(s,a)$ . A critic estimates this value function, off-policy from trajectroeies generated by  $\beta(a|s)$ . Then, in the update, they

calculate....

$$TD_i = r_t + \gamma Q^w(s_{t+1}, \pi_\theta(s_{t+1})) - Q^w(s_t, a_t)$$
(2.31)

$$w_{i+1} = w_t + \alpha_w T D_i \nabla_w Q^w(s_t, a_t)$$
(2.32)

$$\theta_{i+1} = \theta_i + \alpha_\theta \nabla_\theta \pi_\theta(s_t) \nabla_a Q^w(s_t, a_t)|_{a = \pi_\theta(s)}$$
(2.33)

However, it must hold that  $\nabla_a Q^\pi(s,a)$  can be replaced by  $\nabla_a Q^w(s,a)$  without affecting the policy gradient 2.30. This is the case when the gradients are orthogonal, and w minimizes  $MSE(\theta,w)$ . Silver et al [13] suggest to do that via linear regression, however of course we will use ANNs (that then minimize the Mean-squared projected Bellman error by stochatic gradient descent)

What that results to is COPDAC-Q (compatible off-policy deterministic actor critic q learner)

DPG is more data efficient than normal PG, as it doesn't need to take the integral of the actionspace of the policy

WANN BAU ICH DAS BILD EIN????

[analogous, in a policy gradient context, to Q-learnign: it learns a determinsitic greedy policy, off-policy, while exectuging a noisy version of that]

#### Deep DPG

The *Deep DPG Algorithm* is an off-policy actor-critic, online, active, model-free, deterministic policy gradient algorithm for continous action-spaces. The basic idea behind *Deep DPG* (**DDPG**) is to combine the ideas of the DQN (section 2.3) with the architecture put forward by Silver et al. [13] revolving around the deterministic policy gradient. As for that, they also use parameterized deterministic actor function  $\pi(s) = a$  as well as critic function Q(s, a).

The update of the critic is performed analogous to the Q-value approximator in the Deep-Q-Network architecture.  $\langle s_t, a_t, r_t, s_{t+1} \rangle$ -samples are sampled from a replay memory of limited size, to then perform Q-learnig via temporal differences (see 2.16 and 2.17). For that, it is also required to use target networks with the previously mentioned soft updates. Target networks are necessary for both the policy approximator as well as the Q-value approximator [SEE ALGORITHM BELOW].

in combination, that leads to the following update step: The critic minimizes the loss

$$Loss := \frac{1}{N} \sum_{i} \left( \left( r_i + \gamma Q'(s_{i+1}, \pi'(s_{i+1} | \theta^{\pi'}) | \theta^{Q'} \right) - Q(s_i, a_i | \theta^Q) \right)^2$$
 (2.34)

And the actor updates its plicy using the sampled policy gradient:

$$\nabla_{\theta^{\pi}} J \approx \frac{1}{N} \sum_{i} \nabla_{a} Q(s_{i}, \pi(s_{i}) | \theta^{Q}) \nabla_{\theta^{\pi}} \pi(s_{i} | \theta^{\pi})$$
(2.35)

How that looks in an actual Tensorflow implementation can be seen later in this thesis, the corresponding pseudocode is to be found in [8].

Dabieschreiben dass das halt so macht wegen den minibatches? arrg

Using normal Q-learning for the actor leads to the same overfitting problems as it does in DQN, if not using DoubleQ. [Q-learning is prone to overestimating values] -> it did so in ddpg, however they say it still performed well

[hier schon auf wawrzynksi sowie wawrzynksi&tanwani2013 eingehen] [WO im tatsächlichem Netz die actions bei actor und critic reingehen]

#### 2.5 Exploration techniques

As mentioned in the beginning of this chapter, I only considered deterministic policies so far:  $\pi(s) = a$ . In practice however, using purely deterministic policies leads to a complete lack of *exploration* of the state space S of the MDP. Once the agent found a path to a terminal statit will continue *exploiting* this path. In order to explore the full state space, in fact a stochastic policy is necessary.

Blablabla, dass das der Grund ist warum alle unsere algorithmen bisher offpolicy waren - in DQN steht "wir lernen über die greedy argmax policy while performing epsilon-greedy", und in DPG steht auch "the basic idea is to choose actions according to a stochastic behaviour policy (to ensure adequate exploration), but to learn about a deterministic target policy"

von DDPG: "An advantage of off-policy algorithms such das DDPG is that we can trat the problem of exploration independently from the learning algorithm" [VIELLEICHT AM ANFANG SCHON???]

[halt, nachdem ich auf Double, Dueling und DDPG eingegangen bin unbedingt safe auf den Anhang verweisen mit nem vergleich der sourcecodes!] [if Q-learning is off-policy then it does directly approximate Q\*] [dass bei DQN nicht mehr state&action->network->Q-value, sondern state->network->qval1,qval2,...] [GORILA ist 10x so schnell!!]

#### Chapter 3

### Related work

[as mentioned before, there are two levels in the thesis - on the abstract level, the aim is to build a good agent for self-driving cars. On the practical level, it is still one specific simulation of a game, and one at first has to make the given game a RL problem, before you can eben talk about trying to solve that. To show how that is normally done, there is the first section. In the second section I will then talk about successful approaches of self-driving cars in reality. That is at first subdivided into real-life and games. Our game is (like so many others) supposed to work as a bridge between reallife and games. As for that, I will also talk about what data is normally available, ...

#### 3.1 Reinforcement Learning Frameworks

In the previous chapter, I outlined the general structure of a reinforcement learning problem. In summary, it consists of agent and environment, where the environment is discretized into timesteps and only partially observed by the agent (**POMDP**). Each timestep, the agent gets an observation of the environment's state (making up its *internal state* and a scalar reward, and chooses an action to return to the environment. A graphical description of this interaction is depicted in figure 3.1.

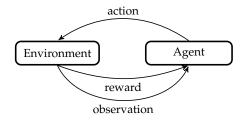

FIGURE 3.1: Interaction between agent and environment in RL

When developing RL agents, it is not enough to create algorithm, but also to have a specification of agent environment that allows for a dataflow as described above. The original Deep-Q-Network [9] as well as its follow-ups [5][15] trained their agents on several ATARI games using the *Arcade Learning Environment* (ALE) [2]. The ALE

was developed with the intention to evaluate the generality of several AI techniques, especially general game playing, reinforcement learning and planning. The important contribution of [2] was to provide a testbed for any kind of agent, by providing a simple common interface to more than a hundred different tasks. The ALE consists of an Atari-Simulator as well as a game-handling layer, which transformed all of the included Atari-games to a standard reinforcement learning problem. Doing that, it provided the accumulated score so far (corresponding to the reward), the information whether game ended (indicating the end of a training episode), as well as a  $160 \times 210$  2D array of 7-bit pixels (corresponding to the agent's observation). As the game screen does not correspond to the internal state of the simulator, the ALE corresponds to a POMDP. The possible input to the simulation consists of 18 discrete actions.

Environments with discrete actions only are however severly limited, and most of the interesting real-world applications, as for example autonomous driving, require however real-valued action spaces. The test scenarios for the Deep-DPG algorithm consisted thus of a number of simulated physics-tasks, using the MuJoCo physics environment.

Both of the above mentioned environments are by now, among many others, merged into the *OpenAI gym* environment [4]. The OpenAI gym¹ is created as a toolkit, helping reinforcement learning research by including a collection of benchmark problems with a common interface. The idea is to provide consistent, standardized environments, such that algorithms are easy to benchmark. In that respect, their goal was to provide the reinforcement-learning-pendant of a labeled dataset, such as ImageNet. Aside the previously mentioned ALE as well as a number of physics tasks using the MuJoCo physics-engine, the openAI gym contains the boardgame Go, two-dimensional continous control tasks (*Box2D games*), a 3D-shooter by the name of *Doom*, and several other tasks. These tasks are varied in their complexity, input and output: some of them use low-dimensional state representations consisting of only a four-dimensional vector of scalars, while others use a 2D-pixel image of RGB colors.

The goal of openAI gym is to be as convenient and accessible as possible. For that, one of their design decisions was to make a clear cut between agent and environment, only the latter of which is provided by OpenAI. The exemplary sourcecode found in algorithm 1, taken from https://gym.openai.com/docs, outlines the ease of creating an agent working in the gym framework. The code outlines how the general dataflow between agent and environment usually takes place: After a reset, the environment provides the first observation to the agent. Afterwards, it is the agent's turn to provide an action. Even though not featured in this easy example, the action is performed by usage of the observation. Once an agent has calculated the action and provided it to the environment, it can perform another simulation step, returning  $\langle observation, reward, done, info \rangle$ , which is a tuple consisting of another observation of the environment's state, a scalar reward, the information if the episode is finished and it is time to reset the environment, as well as some information for debugging, typically not used in the final description of an agent. In the remainder of this work, I will refer to this dataflow as a baseline on how the interaction of environment and agent should look like.

It is worth noting, that the openAI gym is not even

#### 3.2.2 games

Tensorkart hier in den fußnoten die ganzen non-scientific quellen wie tensorkart undso

Das Aufteilen von autonomous driving into the subcomponents, wie bei der vorlesung von Julian... oder, as quoted by TORCS-Paper: "The racing problem could be split into a number of different components, including robust control of the vehicle, dynamic and static trajectory planning, car setup, inference and vision, tactical decisions (such as overtaking) and finally overall racing strategy"

DDPG auf torc hat übrigens im pixel-case nen sehrsehr ählnichen punktestand wie im low-dimensional case (1840 vs 1876 im best case, -393 vs -401 im average case).

#### **Chapter 4**

# **Program Architecture**

The program was written by the author of this work and is licensed under the GNU General Public License (GNU GPLv3). Its source code is attached in the appendix of this work and additionally can be found digitally on the enclosed CD-ROM. The machine learning part was written in PYTHON, using the TENSORFLOW-library [1]. [tf gibt automatic differentiation, multi-gpu support, python interface]

#### 4.1 Design choices

#### 4.1.1 The game as a reinforcement learning problem

-ungefähres UML-diagramm -das spiel itself ist ein partially observable MDP, und es ist (as tested) surprisingly indeterministic

[Ah. Should have googled first before posting. Differences in FPU calculations on different processors. Differences in timing affecting things like the number of times a random number generator is called. These can cause the physics to get out of sync] https://forum.unity3d.com/threads/is-unity-physics-is-deterministic.429778/

- 4.1.2 The vectors

#### 4.2.2 The agent

Unbedingt auf jeden Fall UML-diagramm

#### **Challenges and Solutions**

DQN vs DDPG, sehend vs nicht-sehend, ...

#### **Pretraining**

#### The different agents

sehend vs nicht sehend, ...

#### Network architecture

1. dqn-algorithm - anzahl layer, Batchnorm, doubles dueling - clipping wieder rein, reference auf das dueling - grundsätzlich gegen batchnorm entschieden, siehe reddit post - MIT GRAFIK - Adam und tensorflow quoten, siehe zotero 2. ddpg - anzahl layer, Batchnorm - MIT GRAFIK

-schöne grafik. -auf meien DQN-config eingehen und(!!!) ne DDPG-config machen, using the "experiment details" vom ddpg paper

In the original DDPG-algorithm [8], the authors used *batch normalization* [6] to have the possibility of using the same network hyperparameters for differently scaled input-values. In the learning step when using minibatches, batch normalization normalizes each dimension across the samples in a batch to have unit mean and variance, whilst keeping a running mean and variance to normalize in non-learning steps. In Tensorflow, batchnorm can be added with an additional layer and an additional input, specifying the phase (learning step/non-learning step)<sup>1</sup>. Though Lillicrap et al. seemed to have success on using batch normalization , in practice it lead to unstability, even on simple physics tasks in openAI's gym. As I am not the only one having this issue <sup>2</sup>, I left out batch normalization for good.
